#### Abstract

The spectroscopic measurement of burning stars has been carried out in order to examine the spectra of the stars, the peak intensity profiles of the spectra, the burning time and behavior, and the effect of filters on the attenuation of peak intensity and the excitation purity.

Keywords: firework stars, spectroscopic measurement, burning time, emission spectra, three dimensional expression, peak intensity profile, excitation purity, filter

## Introduction

Light emission and the beautiful colors of burning stars are important effects in fireworks. Shimizu ${ }^{1}$ and Douda ${ }^{2}$ were pioneers in modern research into the colored flames of firework compositions. Subsequently the spectra of colored flames were studied in detail and assigned to the respective emitters by Meyerriecks and Kosanke ${ }^{3}$ and others. Kosanke and Kosanke have published a comprehensive review on the chemistry of colored flames, ${ }^{4}$ and Ingram has carried out color purity measurements on traditional pyrotechnic star formulas. ${ }^{8}$

The burning time and linear burning rate are also important characteristics of stars. The shape of a fire flower of stars in the sky depends on the burning time of the stars. A spherical shape is produced by stars with short burning times and a crown or willow shape with long burning times. The linear burning rate is also important for analyzing the exterior ballistics of burning stars.

Preliminary work on the burning time and linear burning rate was done by Ooki et al. ${ }^{5}$ and Higaki et al. ${ }^{6}$ using a high-speed video camera and a pressure vessel. In the present work, spectroscopic measurement is carried out to study the spectra and burning characteristics of spherical stars.

## Experimental

## Materials

The firework spherical stars used in this work were supplied by Sunaga Fireworks Co. Ltd. All stars are coated with prime for promoting ignition of the star composition.

## Apparatus

The spectrometer PMA-11C5966-31 is a product of Hamamatu Photonics Co. Ltd. The spectrometer is composed of an optical fiber for light intake, photodetector, spectroscope, basic software and data analyzer. The analyzer automatically calculates and records the spectrum, the respective peak wavelength and intensity, the excitation purity, and so on.

The spectrometer is equipped with following functions: exposure time from 20 ms to 32767 ms , averaging repetition from 1 to 32767 times, exposure repetition from 1 to 32767 times, and sensitivity low and high. The dark electric current can be corrected for removing background noise.

The analyzer can print out the emission spectrum at a specified time, the peak intensity profile at a specified wavelength and the three dimensional picture of the spectrum with time.

Figure 1. Setup of measurement system.

The two filters used are products of NELLES GRIOT: 03FNQ099 $(D=0.5)$ and $057(D=1.0)$ with attenuation ratios of 0.344 and 0.112 , respectively. ${ }^{7}$

## Procedure

The setup of the spectroscopic measuring system is shown in Figure 1. A star is placed on a heat resistant brick in a draft chamber and ignited by a torch burner. The tip of the optical fiber of the spectrometer is placed at 2.0 m or 4.0 m from the star. The power sources of the spectrometer and the PC are switched on successively. The measurement conditions such as instrument sensitivity, exposure time, averaging repetition numbers and exposure repetition are set and the dark electric current is measured. The spectrometer measurement is started with the ignition of the star.

## Results and Discussion

## Summary of experimental results

The experimental results are listed in Table 1 and Table 2.

## Examples of three dimensional pictures and peak intensity profiles of emission spectra

Examples of the three dimensional pictures of the emission spectra of stars for a no. 5 shell are shown in Figure 2. We can easily determine the outline of the spectrum and the progress of events from the pictures. In the cases of the stars tested, the peak of incandescent emission was large compared to the other peaks which were due to specific color emissions. Each peak in the color spectrum was broad compared to that observed in the flame from liquid color. ${ }^{?}$

The highest peaks of the color spectra were assigned to $\mathrm{SrCl}(667 \mathrm{~nm})$ for red, $\mathrm{Na}(587 \mathrm{~nm})$ for yellow, $\mathrm{BaCl}(520 \mathrm{~nm})$ for green and CuCl $(440 \mathrm{~nm})$ for blue. ${ }^{3}$ The spectra of the other colors were mixtures of the above-mentioned spectra. The silver color was composed of larger K and incandescent, and smaller Na emissions.

Examples of peak intensity profiles of the emission spectra are shown in Figure 3. The wavelength of the specific color peak was chosen, but for some stars the K peak was used because the intensity of the specific color peak was too small compared to the K peak and inaccurate. The intensity increases sharply at first, reaches a maximum and then decreases slowly. The sharp initial increase may correspond to the spread of the fire over the surface of the star and the slow decrease to the decrease in the diameter of the spherical star. The profiles are not smooth but irregular, probably because of fluctuating burning on the star surface.

## Effect of prime on the intensity profile

Ordinary stars are composed of color composition and prime which covers the color composition in order to promote the ignition of the composition. The burning time of a star is the sum of those of the prime and the composition.
The effect of the prime appears in the pressure profile in the burning of a star in a pressure vessel ${ }^{6}$ and the emission spectrum of a burning star as shown in the present work. In the pressure profile of a burning star in a closed vessel, a sharp pressure rise owing to the combustion of the prime appears in the initial stage of the burning, then the pressure drops a little followed by a moderate pressure peak owing to the combustion of the main color composition.

${ }^{\text {a }}$ PS: Peak saturated.

The spectrum of the color composition and the prime of a star are different and therefore the combustion of the composition and the prime can be differentiated. The main peak of both composition and prime is the incandescent emission peak. The color composition has a color spectrum, but the prime does not.
In the first stage of a star burning, the incandescent peak appears and the color peak or peaks do not. After few moments, a color peak begins to appear. In the prime, a small amount of sodium is a contaminant. But the amount of contaminating sodium is much less than that of the yellow color composition, so there is no problem in differentiating the spectra of the yellow composition and the prime.

An example of plot of the intensity of incandescent ( 766 nm ) and color ( 520 nm ) peaks against time is shown in Figure 4. It can be seen that the start times
of both peaks are different. The incandescent peak appears first. The intensity of the 766 nm peak increases at first showing that the fire spreads over the surface of the prime, then the 520 nm peak intensity starts to increase showing that the color composition ignites from the prime combustion. Then both peaks reach maxima and decrease with time showing that the burning surface of the color composition decreases in the course of combustion with time.

## Excitation purity: reproducibility and dependency on combustion time

The excitation purity of the flame color of a star is important for evaluating the star. The available statistical values of the excitation purities are listed in Table 3 for some stars.

The time dependence of the excitation purity is shown in Figure 5. The initial increase of the

Figure 2. Three dimensional pictures of emission spectra of burning stars.

Figure 5. Plot of excitation purity vs. time.
purity corresponds to the flame spreading over the surface of the prime showing that the purity increases with the luminescence intensity of the incandescent emission.

## Burning time against type and diameter of stars

The burning time is one of important properties of firework stars. The shape of a fire flower of burning stars depends on the speed of ejection from the shell and the burning time of the stars. The stationary and moving burning times of stars were measured previously using a high-speed video camera. ${ }^{5,6}$

In this work, the stationary burning time of stars was measured using a PMA-11C5966-31 spectrometer. The results are listed and shown in Table 1 and Figure 6, respectively.
Though there is some scatter in the measured burning time, the burning time increases with increasing star diameter. If the linear burning rate of a star is assumed constant during the combustion, the burning time will be proportional to the diameter of the star. The average linear burning rate $(r)$ can be estimated from the diameter $(d)$ of a star and the burning time $(t)$ using the following equation:
$r=d / t$
Average linear burning rates from this work are listed in Table 4.

## Effect of filter

The intensities of emission of the stars used in this work were so strong that the most intense peaks of incandescence were often saturated. Two filters were used to avoid this difficulty. The performance of the filters was determined by comparing the peak intensities with and without filters. The

Table 3. Statistical values of excitation purity for some stars.

| Star | Number of tests $(n)$ | Mean (\%) | Standard deviation (\%) | Relative standard <br> deviation |
| :--- | :---: | :--- | :---: | :---: |

| Red peony | 5 | 82 | 1.5 | 0.02 |

Table 4. Average linear burning rate of stars.

| Star | Average burning rate $/ \mathrm{mm} \mathrm{s}^{-1}$ |
| :--- | :--- |
| Silver peony | 14.3 |
| Yellow spangles | 7.7 |
| Light blue peony | 7.1 |
| Pink peony | 6.7 |
| Purple peony | 6.1 |
| Red peony | 5.3 |
| Green peony | 5.1 |
| Silver crown | 5 |
| Silver willow | 3.6 |

results are listed in Table 5. The attenuations achieved by combining two filters $((D=1.0)+$ ( $D=0.5$ )) were 0.05 and higher. The attenuation of the green, yellow, silver, red, blue and light blue peonies was about 0.05 . The other stars showed higher attenuation. At the moment, the reason for the difference is not clear and a subject for study
in the future.
The change in the excitation purity by the filters is not so large for the green, yellow, red, pink, light blue and purple peonies, but large for the silver peony, blue peony and silver crown.

## Conclusions

The burning time, peak spectral intensity and excitation purity of burning commercial firework stars were measured using a spectrometer. The burning time varied with the type and diameter of the stars. The intensity of the specific peaks of the emission spectrum changed with time, and showed fluctuation probably owing to the fluctuating burning at the star surface.

The effect of the prime coating the star surface was shown in the intensity profile of the K and visible color peaks. The 766 nm K peak appeared in the first stage of the star burning corresponding to the combustion of the prime and the visible colored flame peak appeared later. The excitation

Figure 6. Plot of burning time vs. diameter of stars.
purity of the star flame was higher in the yellow and red stars and lower in the silver stars. The relative standard deviation of the excitation purity was smaller in the yellow and red stars and larger in the silver stars. The effect of the filter changed with the type of stars.
